ABSTRACT

The direction and magnitude of soil organic carbon (SOC) changes in response to climate change remain unclear and depend on the spatial distribution of SOC across landscapes. Uncertainties regarding the fate of SOC are greater in high-latitude systems where data are sparse and the soils are affected by sub-zero temperatures. To address these issues in Alaska, a first-order assessment of data gaps and spatial distributions of SOC was conducted from a recently compiled soil carbon database. Temperature and landform type were the dominant controls on SOC distribution for selected ecoregions. Mean SOC pools (to a depth of 1-m) varied by three, seven and ten-fold across ecoregion, landform, and ecosystem types, respectively. Climate interactions with landform type and SOC were greatest in the uplands. For upland SOC there was a six-fold non-linear increase in SOC with latitude (i.e., temperature) where SOC was lowest in the Intermontane Boreal compared to the Arctic Tundra and Coastal Rainforest. Additionally, in upland systems mineral SOC pools decreased as climate became more continental, suggesting that the lower productivity, higher decomposition rates and fire activity, common in continental climates, interacted to reduce mineral SOC. For lowland systems, in contrast, these interactions and their impacts on SOC were muted or absent making SOC in these environments more comparable across latitudes. Thus, the magnitudes of SOC change across temperature gradients were non-uniform and depended on landform type. Additional factors that appeared to be related to SOC distribution within ecoregions included stand age, aspect, and permafrost presence or absence in black spruce stands. Overall, these results indicate the influence of major interactions between temperature-controlled decomposition and topography on SOC in high-latitude systems. However, there remains a need for more SOC data from wetlands and boreal-region permafrost soils, especially at depths > 1 m in order to fully understand the effects of climate on soil carbon in Alaska.

Published by Elsevier B.V.

1. Introduction

As much as half of the world's soil organic carbon (SOC) is stored in northern soils (Tarnocai et al., 2009) and projected increases in air temperature are expected to occur more rapidly at high latitudes (IPCC, 2007). SOC stored in high-latitude ecosystems is a potentially

vulnerable component of the global carbon cycle (e.g. McGuire et al., 2009; Ping et al., 2008b; Schuur et al., 2008; Smith and Fang, 2010; Zimov et al., 2006). In high-latitude regions, high stocks of carbon are held in frozen mineral soils and both frozen and unfrozen peatland soils, all of which are vulnerable to soil warming (Dutta et al., 2006; Ping et al., 1997). Additionally, approximately a quarter of Earth's vegetated land cover is in the arctic and boreal regions (McGuire et al., 2009) so that even soils with low SOC contents can store large amounts of SOC on an areal basis. Despite increasing availability of spatial data products and advances in process-based modeling studies, there remain challenges in basic quantification of soil carbon in relation to soil forming

factors (Jenny, 1941) in high-latitude biomes. This is partly due to a relative scarcity of SOC observations in boreal and arctic regions, which must be extrapolated over large and topographically complex areas. Furthermore, much less emphasis has been placed on SOC below organic horizons, revealing a vertical data gap (Ping et al., 2010). Thus, obtaining baseline soil carbon data at high latitudes is a challenge for our ability to understand and model terrestrial carbon feedbacks to the atmosphere.

In Alaska, not only are soil properties strongly linked to vegetation, topography, and parent material (Ping et al., 2004, 2005; Swanson, 1996; Turetsky et al., 2005), but climate also plays a major role in SOC content across Polar, Boreal, and Maritime ecoregions (Post et al., 1982). For example, data from nine profiles suggest that tundra soils hold the highest non-wetland soil carbon contents (314 to 599 MgC ha⁻¹) followed by southern coastal forests (240 to 437 MgC ha⁻¹) and interior boreal forests (169 to 787 MgC ha⁻¹) (Ping et al., 1997). Differences in SOC between Polar and Boreal ecoregions is due to cryoturbation and permafrost occurrence which are associated with colder climates (see also Bockheim, 2007; Bockheim and Hinkel, 2007; Ping et al., 2008a). In contrast, higher SOC in south-east Alaska compared to the interior may be related to high precipitation and organic inputs (Ping et al., 2002). Therefore, the boundaries between Polar, Boreal and Maritime ecoregions represent interesting gradients in temperature and precipitation that may be affected by climate change, with consequences for soil carbon pools (Harden et al., 2008; Steltzer, 2004; Stottlemeyer et al., 2001; Wilking et al., 2006). Further, since potentially one-third of the SOC in the U.S. is stored in Alaska (Bliss and Maursetter, 2010; Guo et al., 2006), SOC dynamics in this state alone directly impact national and continental scale cycling of terrestrial carbon.

Our assessment of the magnitude and distribution of SOC in Alaska involved several objectives. First, we compiled soil carbon data from a variety of academic and government sources to a 1-m depth to provide the most comprehensive, standardized database of SOC in Alaska to date. Second, we partitioned the variability in SOC across Alaska at the ecoregion, landscape, and ecosystem levels as a means

of assessing the distribution of SOC across the state. Finally, as a first-order (i.e., basic) assessment of SOC variability in Alaska, we evaluated the role of various soil-forming factors, including climate, in controlling SOC distributions using simple univariate statistics and multiple linear regression. Although the study is focused in Alaska, it may be viewed as a case study of pedogenesis and SOC content for similar high-latitude soil environments.

2. Methods

2.1. Soil carbon database

This study uses a variety of soil profile datasets with geocoordinates (Fig. 1) from both academic and government sources (including the State Soil Geographic Database, STATSGO) that differ somewhat in their sampling and lab analysis protocols. Three datasets of total profile SOC, but for different depths, were derived from the database for the purposes of this study: 1) 1-m SOC (Mg ha⁻¹), which included the summed SOC of all horizons from the top of the organic layer to the depth of bedrock or 100 cm depth ($n=554$), 2) 50 cm mineral SOC, calculated for the 0–50 cm mineral depth below the organic–mineral interface ($n=603$), and 3) organic layer soil carbon ($n=592$). References to SOC content are for the 1-m SOC pool unless otherwise noted. Most profiles were sampled by horizon type while a smaller number were sampled at fixed depths.

Soil carbon content in most soil profiles were calculated by simply adding together soil carbon content of individual layers. However, bulk density measurements were missing from 40% of the sampled layers in the combined dataset (15% organic and 25% mineral). To fill in gaps, predictive models were developed that estimate bulk density from carbon concentration (%) in mineral soils and carbon content (gC cm⁻²) in organic layers (Appendix 1). Equations were sought that would apply to specific horizons and, in some cases, for specific ecoregions. An uncertainty analysis was also carried out to assess if propagated model errors would affect ANOVA test results (below).

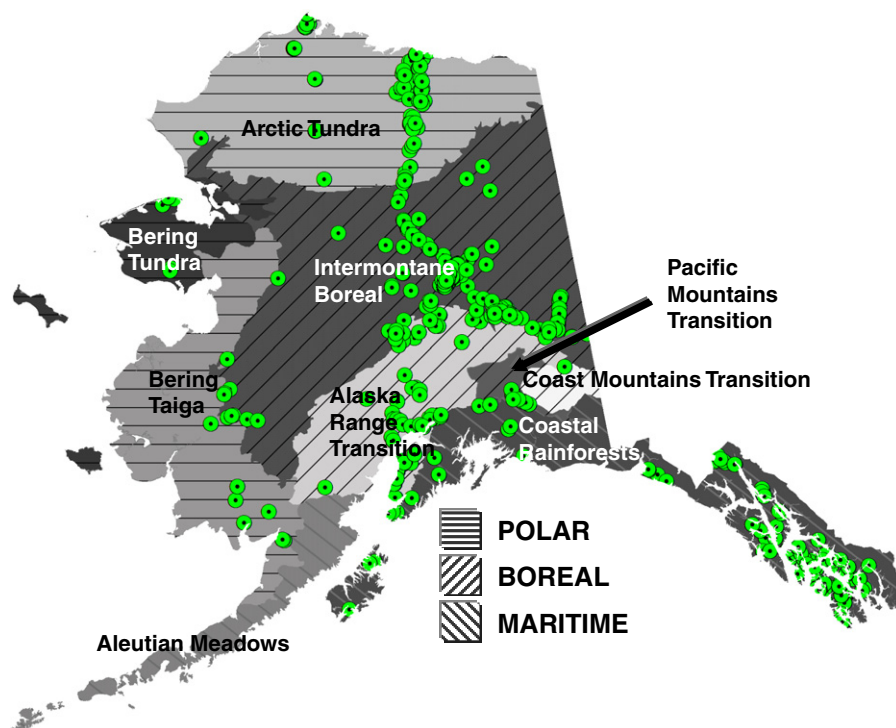

Fig. 1. Locations of soil profiles and ecoregions used in the study. Gray areas and their labels indicate Level 2 ecoregions. Cross-hatching patterns indicate the Level 1 categories—Polar, Boreal, and Maritime.

After the adjustments and predictions from Appendix Table 1 were made, soil carbon content (SOC) (Mg ha^{-1}) was calculated by the equation:

$$\text{SOC} = 100 * (\text{thickness} * \text{carbon} * \text{bulk_density})$$

where *thickness* is of the soil layer (cm), *carbon* is the concentration of total carbon measured by dry combustion (%) (or adjusted from wet combustion, see Appendix 1), and *bulk_density* is for the <2 mm fraction (g cm^{-3}). Where data for the >2 mm fraction was available, the equation was adjusted to calculate carbon content. For about 25% of the profiles it was uncertain whether coarse fragments were present in the profile. A correction factor of 0.01, based on available empirical data, was applied to the SOC content of some profiles where this information was not available but where it was likely that rock content was high. However, we recognize that this figure may be low for some till substrates (see sensitivity analysis below).

Calculating SOC using the above equation cannot always be applied to highly cryoturbated soils in the Arctic Tundra region. Therefore, for cryoturbated profiles only, published values for the total 1-m pool were directly added to the database. A simple ratio was applied to the “mineral” part of the soil (the 1-m SOC minus the surface organic layer) to approximate organic carbon content of the 0 to 50 cm mineral soil carbon content for cryoturbated profiles only (50cmSOC , Mg ha^{-1}):

$$50\text{cmSOC} = (1\text{mSOC} - \text{OlayerSOC}) * \frac{50\text{cm}}{(100\text{cm} - \text{OlayerDepth})},$$

where 1mSOC is the total soil carbon content (including the organic layer) to a 1-m depth (Mg ha^{-1}), OlayerSOC is the surface organic layer soil carbon content (Mg ha^{-1}), and OlayerDepth is the depth of the organic layer (cm, ≤ 100 cm). This approach assumes an equal distribution of SOC in cryoturbated soils with depth (c.f. Michaelson et al., 1996; Bockheim and Hinkel, 2007). Surface organic layer carbon in Arctic regions that was not subsumed into the mineral matrix was calculated in the same manner as non-cryoturbated profiles.

2.2. Ecoregions in Alaska

The study includes data from the entire state of Alaska, divided by various levels of ecoregions as defined by Nowacki et al. (2001) (Fig. 1). Thirty-two ecoregions (“Commoners”) were delineated along climate and vegetation gradients. These are grouped into three Level 1 regions, “Polar”, “Boreal”, and “Maritime”, and nine Level 2 regions. Much of the current study is focused on four Level 2 ecoregions, “Intermontane Boreal”, “Arctic Tundra”, “Alaska Range Transition”, and “Coastal Rainforests”, because of the richness in observations in these areas. The distribution and areal extent of Level 2 ecoregions are similar to the Major Land Resource Areas (MLRA’s) used by the Natural Resources Conservation Service (USDA, 2006). Level 1 and Level 2 regions were used in combination with land cover and landform classes for exploring data gaps, and for discussing broad scale changes in SOC across the state. Geography, climate regimes, geology, vegetation cover and fire activity distinguish ecoregions and their soils. The Intermontane Boreal, unlike other parts of Alaska, was never glaciated but is well marked by braided rivers from glacial runoff from adjacent regions (Ping et al., 2006).

2.3. Proxies for soil forming factors

Site attributes such as vegetation cover, parent material, soil drainage, slope and aspect were inconsistently recorded in the datasets. Therefore, for the purposes of this study, soil forming factors were represented by mostly GIS information which was overlaid and extracted to point observations. The level of accuracy of this approach depends on the type of information and scale of the data layer from

which it was extracted (see below). All data extractions were performed in the Alaska Albers Equal Area Conic projection with North American Datum 1983 using ArcInfo software (Environmental Systems Research Institute, 2010).

2.3.1. Landcover

Landcover data were obtained from the 30 m National Landcover Database (2001 NLCD; Homer et al., 2004) for the year 2001. The NLCD has been used previously in the study of state factor effects on soil carbon distribution in the conterminous U.S. (Guo et al., 2006). Most of the soil-bearing areas in Alaska are defined by categories of “evergreen forest”, “deciduous forest”, “mixed forest”, “shrub/scrub”, “dwarf shrub”, “sedge”, “woody wetland”, and “emergent herbaceous wetland”. For some analyses, the three forest classes and two shrub classes were each combined into two general classes—“forest” and “shrub”. For Intermontane Boreal analyses, evergreen forest was separated into “black spruce” and “white spruce” based on field notes. The 2001 NLCD vegetation cover is highly correlated with topography. For example, deciduous forests will occur mostly on south and west facing aspects in upland areas and in locally well-drained lowland locations. Shrubs occur under a variety of conditions including cold upland slopes, lowland black spruce woodlands, and recently disturbed areas (i.e. floodplains, fire scars) (Edwards and Armbruster, 1989; Viereck et al., 1983).

The NLCD land cover classes extracted to observation points were generally consistent with field observations, when such observations were available. Much of the initial misclassification was due to discrepancies between the sampling date and the date of the 2001 NLCD (e.g., soils sampled on forested lands that were later commercially developed). Profiles were sampled mostly between the years 1980 and 2010 and less than 10% of them were sampled as early as the 1950’s. Field notes were available for only 77% of the observations. From the observations with field notes, we were able to determine that 56% of them were identified correctly by the NLCD map. If we apply this ratio to the remaining observations with no field notes, then we predict that 90% of the observations were likely correctly identified. It is important to note that land cover in this study was not used as a predictor variable, but rather to stratify data.

2.3.2. Proxy for parent material and topography

Landform type for each of the observations was assigned and defined from parent material texture, digital elevation model (DEM), and land cover layers. A 60 m USGS DEM of Alaska was re-sampled to 1 km for efficiency in creating landform classes. Landforms were defined in such a way as to represent broad categories of soil drainage conditions that are common in Alaska. Although this approximation of soil drainage may be crude at the point scale, it represents larger scale drainage in the surrounding landscape. Further, this approach relies on raster DEM-derived attributes of topography (e.g. slope) instead of STATSGO soil map units which are still only coarsely mapped in Alaska (Bliss and Maursetter, 2010).

The parent material, DEM and land cover layers were combined to develop discreet landform units using the following steps. First, parent material texture—“Rocky or Variable”, “Sandy” and “Silty”—mapped by Jorgenson et al. (2008) was extracted to each of the observations. In the Intermontane Boreal, areas mapped as Sandy and Silty were mostly river floodplains, or areas adjacent to floodplains. In contrast, Sandy and Silty sources in the Arctic Tundra were mostly marine deposits. Till made up most of the Rocky or Variable textures that occurred nearly everywhere else in the state. Second, slope and topographic position index (TPI) from the 1 km DEM (USGS) were combined to delineate upland and lowland areas. Topographic position index is essentially a measure of hillslope position where positive values represent topographic high points (e.g. ridges) and negative values are topographic low points (e.g. valleys) (Weiss, 2001). It is calculated as the difference of a cell’s elevation and the mean elevation of a

ring of cells around it (using the Benthic Terrain Modeler tool for ArcMap; Wright et al., 2005). Slope (%) further distinguishes landform type where gently sloped areas and topographic low points are considered lowlands while moderately and steeply sloped areas are uplands. Formally, “Upland” areas were defined as: 1) $TPI \geq 4$ and $slope \geq 0$ and 2) $TPI < 4$ and $slope \geq 10$. “Lowland” areas were defined as $TPI < 4$ and $0 < slope < 10$. Third, Upland and Lowland classes were combined with the Rocky, Sandy and Silty classes. This resulted in five combinations—“Rocky or Variable Upland”, “Rocky or Variable Lowland”, “Sandy Upland”, “Silty Upland”, and “Silty Lowland” (“Sandy Upland” is a rare combination in Alaska and was ignored in this study). Rocky or Variable Uplands and Rocky or Variable Lowlands together comprise 62% of the state and can be thought of as general categories where the “Sandy” and “Silty” modifiers do not apply. For convenience, we refer to Rocky or Variable landforms as simply “Uplands” and “Lowlands”. Lastly, “Wetlands” were distinguished from other lowland areas by superposing “emergent herbaceous wetland” and “woody wetland” NLCD land cover classifications on each observation, regardless of its previous classification under the first two steps.

2.3.3. Proxy for climate

Climate information was obtained from the Parameter-Elevation Regression on Independent Slopes Model (PRISM), a product of Spatial Climate Analysis Service at Oregon State University (Daly et al., 2001). PRISM algorithms account for important spatial differences in Alaskan climate such as winter inversion, coastal proximity and elevation. The spatial resolution of monthly air temperature and precipitation are 2 km and averaged from 1961 to 1990. In addition to mean annual temperature and precipitation (MAT, MAP), mean summer (June, July, August; MST, MSP) and winter (December, January, February; MWT, MWP) temperature and precipitation were also derived and extracted to each soil carbon observation. Growing season length (GSL) was derived from the number of days between the date of thaw and date of freezing. Additionally, MST–MWT was derived and used as an index of continentality (Kauppi and Posch, 1985) and indicator of shifting seasonal climatic regimes and fire activity. Surface air temperatures can be problematic proxies for soil temperature which largely control productivity and decomposition because of the influence of organic layer and snow depth and other topographic variables (e.g. Jorgenson et al., 2010; Yi et al., 2009). However, for broad regional comparisons, these variables may correlate with soil temperature and processes which govern SOC storage (e.g., Bond-Lamberty and Thomson, 2010; Guo et al., 2006).

2.3.4. Other climatic, biotic, and topographic proxies

Folded aspect was calculated to reflect heat load differences where southwest facing slopes (225° clockwise from North) are the highest and northeast facing slopes (45°) are the lowest (McCune and Dylan, 2002):

$$folded\ aspect = |180 - |aspect - 225||.$$

Profiles that had permafrost in the top 1-m of soil and those without permafrost were labeled accordingly for means comparisons. Most of the profiles in the dataset (81%) did not have permafrost in the top 1-m of soil. Active layer depth was not consistently measured across all the observations. In the few cases that it was noted it was calculated as the depth from the top of the surface organic layer to the top of the perennally frozen layer (denoted by “f”). Stand age was also noted inconsistently. However fire perimeters and the year of fire events have been mapped for Alaska since 1943 (BLM, 2008) and were used to approximate stand age for observations where this information was missing. Stand ages were then grouped as “young forests” (<65 years) or “mature forest” (>65 years) for means comparisons and controlling for stand age effects in the presence of other predictors.

2.4. Data analysis

Comparisons of SOC were made at various scales within Alaska (i.e. levels of ecoregion, landform, and ecosystem partitioning) in addition to global SOC means. Differences in SOC content were assessed in a way that mimicked experimental control of temperature and landform. After individual profiles were assigned to specific ecoregions and landforms their SOC contents were assessed with one-way analysis of variance (ANOVA) tests. In each comparison, the data were log transformed to correct for data skewness and unequal variances were tested with the Levene test. When data distribution followed the assumptions of normality and approximately equal variances, the Tukey–Kramer HSD test was used at $P = 0.05$. If variances were found to be unequal, a Welch’s ANOVA test was applied allowing for unequal standard deviations. If variances were unequal and the sample population not normally distributed, then the Wilcoxon rank-sum test was applied. In all cases where post-hoc analysis was required, the appropriate Bonferroni statistic was used to determine statistical significance.

To control for landform, ecoregion was treated as the fixed effect for each landform. Similarly, to control for ecoregion, landform was treated as the fixed effect within a specific ecoregion. The same approach was used to compare SOC between vegetation types within the same landform and ecoregion. In addition to comparing SOC between Level 2 ecoregions for specific landforms, SOC was also compared without consideration of landform, i.e. a lumped ecosystem average. Partitioning profiles sometimes resulted in small groups, therefore, a cutoff of <5 profiles per group was used to determine if the group would be included in the ANOVA tests. To assess multiple effects on SOC, multiple linear regression was used to relate both climatic variables and organic layer depth to SOC content within Alaskan forests. All possible models with a maximum of two or three terms were assessed to find significant, parsimonious models of SOC distribution. Several tests were used to select the best fit models of SOC in Alaskan forests: 1) adjusted R^2 , 2) root mean squared error (RMSE), and 3) corrected Akaike’s Information Criterion (AICc). All statistical analyses were carried out with JMP software (SAS, version 8.0).

The model and overall approach used in this study to calculate individual profile SOC is somewhat complex and there is a possibility that model error may affect our comparisons of means across landforms and ecoregions (Appendix 1). Therefore, to address this, we applied a Monte Carlo method of propagating errors (Yanai et al., 2010) and observed what effect this had on the ANOVA tests applied for comparing mean SOC in the 1-m pool across ecoregions for specific landforms. For each iteration, we randomly applied the standard errors from the models of $\%C_{tot}$ and Th (Appendix Table 1) simultaneously to each profile that required gap-filling. Then, new group comparisons were performed for all of the profiles in the same way as outlined above. After these steps were repeated 100 times, we found that the range of p-values never changed the results of the comparisons.

We performed additional analyses to understand the effect of certain deficiencies in the dataset in several ways. First, 178 profiles from Table 2 needed no gap-filling and could therefore be used as validation. When measured 1-m SOC was compared to predicted SOC, the slope was not significantly different than 1 ($P = 0.05$), although 8 of the profiles had predicted SOC that was 50 to 80% different from the measured value. Several of these outliers were peatland soils and so it is possible that the gap-filling approach may underestimate SOC at these locations. Second, to assess the effect of adjusting $\%C_{org}$ on mean 1-m SOC, we compared three approaches of calculating mean 1-m SOC from 29 profiles where $\%C_{org}$ and $\%C_{tot}$ overlapped: 1) using $\%C_{tot}$ only, 2) using $\%C_{org}$ only, and 3) using $\%C_{adj}$ only. All of the approaches yielded SOC estimates that were <1% different from each other. Third, about 12% of the layers were known to have $pH \geq 7.5$ (30% of the layers had no pH data), but few layers were analyzed for carbonates. For profiles that had pH measurements ($n = 39$), when calculations of profile SOC included carbonates the mean SOC was 1.3% lower than when the

carbonates were not included. Therefore, a few profiles with high pH were likely underestimated by this amount. Lastly, recall that for about 25% of the profiles it was uncertain whether coarse fragments were present. Mean SOC calculated without coarse fragments was 4.4 and 3.2% higher than mean SOC calculated with coarse fragments in the Silty Lowlands and Sandy Lowlands, respectively. The same calculations showed that Uplands and Lowlands were 1.4 and 1.0%, higher, respectively, when coarse fragments were omitted. Therefore, for this subset of data where coarse fragments were missing, soils with sandy or silty parent materials could be somewhat overestimated even after our correction was applied. Overall, these analyses support that errors resulting from our approach in calculating SOC means are probably small for the purposes of comparing group means, although individual profiles may not be well predicted in some cases.

3. Results

3.1. Representativeness of dataset relative to Alaska landscapes

Data were richest in four of the five largest Level 2 regions in Alaska, the Intermontane Boreal, Coastal Rainforests, Arctic Tundra, and Alaska Range Transition, and profile data were generally proportional to areal coverage of each ecoregion (Fig. 2a, b). The exception was the third largest ecoregion, the Bering Taiga, which was poorly sampled. Most of this region is covered with shrubby vegetation (65%) with lesser coverage from forests (14%) and wetlands (14%). Other poorly sampled Level 2 regions included the Bering Tundra and Aleutian Meadows which together make up 9% of Alaska.

Observations of 1-m SOC were generally well distributed across climate gradients for specific landform types, but there were several exceptions (Fig. 3). There were no observations in Silty landform types of the Brooks Foothills where the mean MAT is -12°C and MAP is 230 mm. Additionally, while Silty Lowland observations were sampled regularly across the gradient from -7 to -1°C , Silty Uplands had only two observations throughout the gradient. The undersampled Silty landforms in northern and central Alaska were predominantly loess deposits, especially in the lower Brooks Foothills, Kuskokwim Mountains and Yukon River Lowlands. Further, although there was notably good coverage of SOC observations for emergent wetlands near Barrow, AK (-12.5°C MAT, 180 mm MAP), observations were generally missing for the wider and more common climate gradient for wetlands found in the Arctic Tundra (-12.5 to -10°C MAT, 180 to 400 mm MAP).

Combining data by Level 1 regions, land cover, and landform data resulted in 33 unique combinations that described 90% of Alaska's landscape (Fig. 4a,b). However, soil profile observations were not distributed evenly across the classes. For example, approximately 43% of Alaska

is covered by shrubs with rocky parent material, yet only 9.5% of the observations fall in this category. Although there were 25 emergent wetland observations to a depth of 1-m or more in the Polar regions, there were only 6 for the entire Boreal region. Other relatively sparsely sampled combinations (<5 observations) that made up at least 3% of Alaska's landscape were the Boreal Lowland Shrubs and Polar Silty Lowland Shrubs. For the Maritime region, poorly sampled combinations included only the Lowland Shrubs. In contrast, some environments were sampled more densely, including the Polar Sedges (both upland and lowland), Maritime Evergreen Forests (both upland and lowland), Boreal Sandy Lowland Evergreen Forests, and Boreal Deciduous Forests (both upland and lowland).

It was unclear how well soil carbon contained in permafrost to a 1-m depth was represented by the dataset, especially in Boreal regions. According to the National Cooperative Soil Survey (NCSS) horizon designation convention (used for 92% of the dataset), permafrost is indicated by an "f" (i.e. "frozen") in the soil layer sampled (Schoeneberger et al., 2002). In the Arctic Tundra 75% of the observations documented permafrost within the top 1-m of soil. In the Intermontane Boreal, however, only 18% were noted as having permafrost. We note that some profiles were not sampled to a 1-m depth (and therefore not included in our analysis) possibly due to permafrost inhibiting deeper sampling. Therefore it is possible that the proportion of profiles containing permafrost in our dataset is somewhat biased and may be higher. Moreover, we also note that the current dataset does not include permafrost or carbon deeper than the 1-m cutoff as these samplings were rare.

3.2. Distribution of SOC by ecoregion, landform, and ecosystem for selected ecoregions

3.2.1. Partitioning SOC by ecoregion

Within the most data-rich Level 2 ecoregions, mean 1-m SOC varied significantly ($P < 0.05$), showing a three-fold difference from 140 Mg ha^{-1} in the Intermontane Boreal to 440 in Arctic Tundra (Fig. 2c). High SOC content was also observed in the Alaska Range Transition (260 Mg ha^{-1}) and Coastal Rainforests (250 Mg ha^{-1}), but these were still 1.7 and 1.8 times lower than the Arctic Tundra. Although sparsely sampled, the Bering Taiga and Bering Tundra regions had somewhat lower mean 1-m SOC (not significant $P > 0.05$) than the Arctic Tundra. Likewise, the Pacific Mountains Transition region (i.e. the Copper River Basin) was very similar in SOC levels to the Intermontane Boreal.

3.2.2. Partitioning SOC by landform

Partitioning the variability of 1-m SOC by landform (the combination of topographic and parent material characteristics) resulted in an almost seven-fold difference among means ($P < 0.0001$) (Table 1). The

Fig. 2. Area, data coverage, and 1-m SOC measurements for Level 2 ecoregions in Alaska. The histograms represent (a) the percent soil-bearing area and (b) the number of observations to a 1-m depth within each ecoregion. Box plots for SOC observations (c) represent the 90% data intervals, inter-quartile ranges and medians.

Fig. 3. Plot of climate conditions for soil profiles used in this study by landform type. Contours indicate the percentage of land across Alaska. The outermost contour captures the area representing 90% of Alaska's soil bearing landscape while the innermost contour corresponds to 10% of the landscape (contour intervals of 10%).

highest mean 1-m SOC was in the Arctic Tundra Uplands with 533 Mg ha^{-1} and the lowest was in the Intermontane Boreal Uplands with 86 Mg ha^{-1} . The Arctic Tundra Uplands were also 2.5 and 2.2

times the mean SOC in Uplands of the Alaska Range Transition (210 Mg ha^{-1}), and Coastal Rainforests (240 Mg ha^{-1}), respectively. Similarly, Sandy Lowlands of the Arctic Tundra (511 Mg ha^{-1}) and

Different lower case letters indicate significant differences ($P < 0.05$) between landform types of the same ecoregion.Different upper case letters indicate significant differences ($P < 0.05$) between ecoregions of the same landform type.^a Samples < 5 were omitted from comparisons.^b Excludes observations from the Brooks range for comparability across landform types.^c Excludes observations from the Alaska range for comparability across landform types.

Alaska Range Transition (376 Mg ha^{-1}) regions were 4.5 and 3.3 times higher than the Intermontane Boreal region (113 Mg ha^{-1}). Also, the Silty Lowlands were 1.9 times higher in the Alaska Range Transition (283 Mg ha^{-1}) than in the Intermontane Boreal (152 Mg ha^{-1}). The Lowlands were only significantly different in their SOC content between the Arctic Tundra and Intermontane Boreal. In contrast, there were no differences among Arctic Tundra and Intermontane Boreal Wetlands.

Within ecoregions, the largest difference in 1-m SOC among landforms occurred in the Intermontane Boreal between the Wetlands (381 Mg ha^{-1}) and all other landforms, being 4.4, 3.4, 2.5, and 2.0 times larger than the Uplands, Sandy Lowlands, Silty Lowlands (152 Mg ha^{-1}), and Lowlands (194 Mg ha^{-1}), respectively (Table 1). Similarly, the Intermontane Boreal Lowlands were 2.3 and 1.7 times higher than the Uplands and Sandy Lowlands. No differences in SOC were observed in the Coastal Rainforest landforms. Sandy Lowlands of the Arctic Tundra were significantly higher than other Lowlands, but Sandy Lowlands were also spatially distributed towards the northern edge of Alaska where temperatures were colder.

3.2.3. Partitioning SOC by ecosystem

When 1-m SOC was partitioned by ecosystem (i.e. local-scale combinations of ecoregion, landform, and vegetation), there was more than a 10-fold difference among means that was highly significant ($P < 0.0001$) (Table 2). There were low sample numbers for some groups; however, dominant environments within specific ecoregions were still represented (see Fig. 4 for box plots of similar Level 1 ecoregion ecosystems). Mean 1-m SOC was highest in Arctic Tundra Sedge Uplands and Sandy Lowlands (729 and 519 Mg ha^{-1}) and lowest in Intermontane Boreal White Spruce, Mixed Forest and Deciduous Forests (69 , 74 and 81 Mg ha^{-1}) (Table 2).

When holding ecoregion and landform constant, the largest and most significant ($P < 0.05$) differences between vegetation types occurred in the Intermontane Boreal, where in the Sandy Lowlands Black Spruce (288 Mg ha^{-1}) and White Spruce (134 Mg ha^{-1}) were 3.1 and 1.5 times higher, respectively, than Mixed Forest (92 Mg ha^{-1}) (Table 2). Both the organic and mineral SOC pools contributed roughly equally to the higher SOC observed in Sandy Lowland Black Spruce compared to other Sandy Lowland vegetation types. Similar differences were observed between Upland Black Spruce and other species (Table 2). However, these differences were not significant and we note that only five black spruce observations were available for this comparison. In contrast, the Coastal Rainforests showed little

change across Upland ecosystems except that Lowland Sitka Spruce (248 Mg ha^{-1}) was 1.6 times higher than Lowland Mixed Forest (152 Mg ha^{-1}).

Some forest types that occur over a variety of landforms were compared by holding ecoregion and vegetation type constant. Both Deciduous and White Spruce types in the Intermontane Boreal had higher 1-m SOC in the Sandy Lowlands compared to the Uplands (Table 2). There were no significant differences among other landform and vegetation combinations, including all black spruce types.

3.3. Factors affecting SOC accumulation

3.3.1. Climate and SOC interactions in uplands and lowlands

Soil carbon contents changed dramatically, but non-linearly in Upland and Lowland landforms across a latitudinal gradient represented by selected ecoregions (Table 1; Fig. 5a,b). Concurrently, vegetation changed from sedges and shrubs to forest, reflecting warmer soil temperatures related to higher MAT (Fig. 5c) and GSL. Precipitation also increased steadily, until the Coastal Rainforest, where it increased sharply (Fig. 5d). The magnitude of SOC changes was greater in the Uplands than in the Lowlands. Indeed, the change was only significant between Intermontane Boreal and Arctic Tundra Lowlands for both the 1-m and 50 cm mineral pools (Table 1).

3.3.2. Climate and SOC interaction by ecosystem–boreal forest regression models

Regression models were successful at showing that climate variables affect 50 cm mineral SOC (Table 3). However, the collinearity of several of the climate variables limits our interpretation of exactly which one is responsible for driving SOC changes. The Upland forests of the Intermontane Boreal and Alaska Range Transition are two contrasting ecoregions that comprise most of the Boreal dataset. The Intermontane Boreal has higher MST (Fig. 5c) and fire frequency, but lower GSL. The degree of continentality (i.e. MST–MWT) alone explained 69% of the variation of 50 cm mineral SOC and 46% in the 1-m SOC pool. In another model, GSL and MST explained 73% of the variation (Table 3). These relationships were consistent even when analyzed separately within each ecoregion where the GSL and MST model explained 30% and 42% of the variation in the Intermontane Boreal and Alaska Range Transition, respectively, with all parameters remaining significant ($P < 0.01$; not shown in Table 3). Adding the log-transformed thickness of the organic layer to the first GSL and MST

regression improved the model fit (Table 3), where the parameter was positive and highly significant ($p = 0.0053$).

Models with MAP, MSP and MWP did not improve the model R^2 as GSL and MST were always the most significant variables models. Nevertheless, a highly significant model with GSL and MAP, with both parameters positive, still explained 64% of the variation (Table 3). Similar Lowland models were found, but they were always weaker than the Upland models (adj. R^2 near 0.1). Adding GSL or MST interaction terms into the regression models above did not improve the model fit or achieve greater model significance.

3.3.3. Aspect

Differences in 1-m SOC between aspect classes were largest within the Arctic Tundra and Coastal Rainforests (Table 4). Soil profiles located in Arctic Tundra NE aspects (565 Mg ha^{-1}) in Sandy Lowlands contained 1.3 times more SOC than those located in NW/SE aspects (427 Mg ha^{-1}). Further, also for Arctic Tundra Sandy Lowlands, folded aspect was significantly correlated with 50 cm mineral SOC ($P = 0.0006$) and explained 22% of the variation in this pool. NE (302 Mg ha^{-1}) and NW/SE (291 Mg ha^{-1}) aspects were both approximately 1.7 times higher than SW aspects (174 Mg ha^{-1}) in the Coastal Rainforest Lowlands. The largest difference observed in the Intermontane Boreal was in the Uplands, where SW aspects (121 Mg ha^{-1}) were higher than NW/SE aspects (77 Mg ha^{-1}) by a factor of 1.6, and was due mostly to changes in the mineral SOC pool. No other significant differences across aspects were observed in the Uplands of other ecoregions. This is despite the fact that a large variation in solar radiation occurs in the Uplands and may suggest that sampling was too limited across aspect types (Table 4).

3.3.4. Permafrost

Although the presence and depth of permafrost and active-layer depth (ALD) were incomplete, at least one comparison was possible within a single vegetation type: black spruce forests. Soil organic carbon was 1.4 times higher ($P < 0.05$) under black spruce with permafrost present in the top 1-m of soil (262 Mg ha^{-1}) than black spruce without permafrost (186 Mg ha^{-1}). This difference was apparently due to higher SOC in the organic layer because there was no significant difference in the 50 cm mineral SOC pool ($P > 0.1$). From limited ALD data, mean Boreal ALD was much greater (69 cm) than Polar soils (44 cm) ($P < 0.0001$).

3.3.5. Fire

There were no profiles located in areas that had been burned within the last 65 years outside the Intermontane Boreal region. Burned profiles were lower in 1-m SOC than unburned, but only for Sandy Lowland (53 vs. 141 MgC ha^{-1} ; $P < 0.0001$) and Upland (66 vs. 93 MgC ha^{-1} ; $P < 0.05$) landforms. In Sandy Lowlands, both organic layer SOC and 50 cm mineral SOC were significantly lower in burned than unburned profiles ($P < 0.01$). However, in Uplands, only organic layer SOC of burned profiles was significantly lower than unburned ($P < 0.01$), while 50 cm mineral SOC showed no difference ($P > 0.1$).

4. Discussion

4.1. Representativeness and data gaps

The collaborative data collection effort used in this study resulted in a generally representative dataset of many of Alaska's soils by area. There was generally good coverage of the Uplands and Lowlands

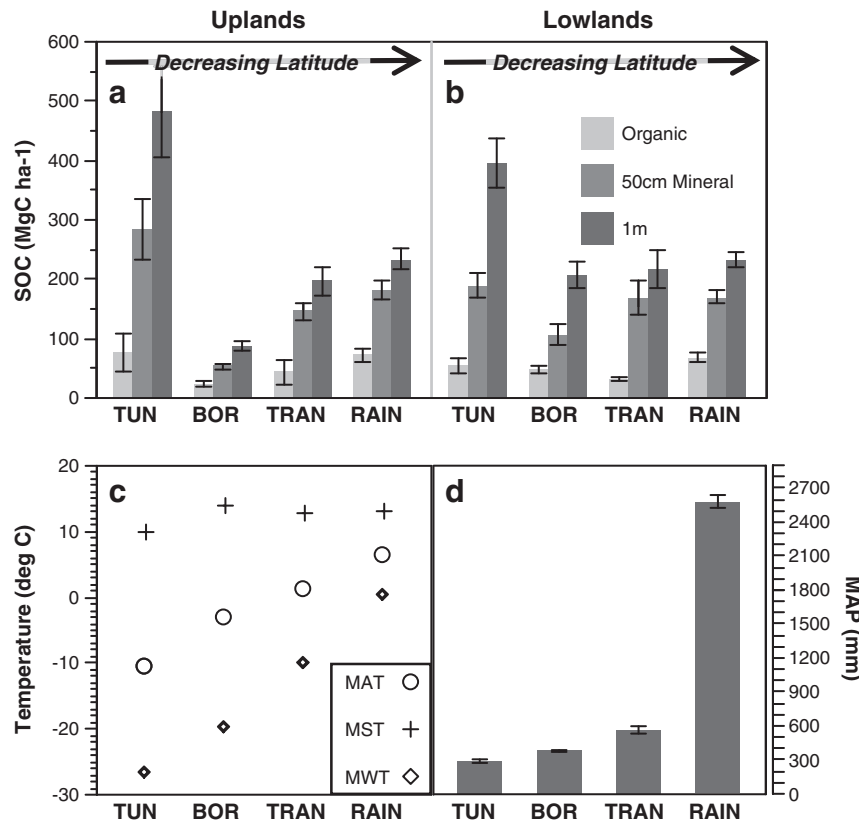

Fig. 5. Soil organic carbon content (organic, 50-cm mineral, and 1-m) in (a) Upland and (b) Lowland landscapes across Level 2 ecoregions. (c) Mean annual temperature (MAT), mean summer temperature (MST), mean winter temperature (MWT) and, (d) mean annual precipitation for the selected profiles across ecoregions. TUN—arctic tundra, BOR—Intermontane Boreal, TRAN—Alaska Range Transition, RAIN—Coastal Rainforest. Bars added to summed variables represent the standard errors of the means. High elevation profiles in the Brooks and Alaska ranges, and profiles under forests <65 years old, were removed for comparability.

(of Rocky or Variable soil parent materials) which cover 62% of the state. However, our findings suggest that areas of highest SOC content and highest SOC variability, i.e. permafrost and wetland locations (Rapalee et al., 1998; Tarnocai et al., 2009; Turetsky et al., 2005; Zimov et al., 2006), are still under-sampled. More precise delineation of parent material type and extent than was used in this study is needed to extrapolate where permafrost occurs and at what depth, especially in the Intermontane Boreal. Knowing permafrost depth and spatial extent would facilitate an understanding of how permafrost is distributed in relation to SOC densities (g cm^{-3}) within the soil profile. It remains uncertain how sensitive deeper than 1-m SOC pools are to future climate changes (McGuire et al., 2009; Schuur et al., 2009; Tarnocai et al., 2009). Given

the potential ecosystem consequences of permafrost thaw, the spatial distribution and quantification of permafrost SOC remains an important knowledge gap (Davidson and Janssens, 2006; Hinzman et al., 2006; Schuur et al., 2008).

The three-fold differences in SOC observed in the Sandy Lowlands under different vegetation types indicate the high spatial variability of soil drainage classes within lowland areas. Wetlands, peatlands, and other adjacent lowlands are complex and dynamic environments where land cover, permafrost distribution, and drainage change dramatically within small spatial scales (Turetsky et al., 2005). These environments are further impacted by fire which can change soil properties quickly (Harden et al., 2000, 2006; Swanson, 1996). If fire frequency increases in Alaska due to future climate warming (Balshi et al., 2009), alterations in land cover and soil drainage (e.g. thermokarst or talik development) will likely affect Alaska's SOC contents and spatial distributions (Harden et al., 2000; Jorgenson and Osterkamp, 2005; Jorgenson et al., 2001). Further sampling in these areas will help reduce the uncertainty in the fate of lowland SOC in response to fires and other climate-driven factors.

The distribution of roads in Polar and Boreal Alaska has made it possible to sample soils over latitudinal gradients that cross a variety of climate regimes, landforms and vegetation types (Fig. 1). However, noticeably missing are observations across longitudinal gradients that are more representative of continental effects on climate regimes. The importance of continentality is partly indicated by the negative relation of MST–MWT and SOC in the Upland forests found in this study (Table 3). The north–south distribution of observations is less ideal because interior Alaska is bounded by the Brooks and Alaska Ranges which separate different climate patterns. For example, MAT and MAP tend to be more strongly positively correlated to each other in the Arctic Tundra than in the Intermontane Boreal and Bering Tundra. Although the Arctic Tundra and Bering Tundra are similar in vegetation composition and

parent material, the Bering Tundra is much warmer due to higher solar radiation and a longer growing season. Thus, there is reason to be cautious about assuming that SOC contents in the Arctic Tundra represent SOC for the Bering Tundra.

Despite the vast coverage of shrubby land covers across Alaska (56%; Fig. 4), this vegetation type was sparsely sampled. Shrub cover in the Boreal and Polar regions has expanded in recent decades (Sturm et al., 2001; Tape et al., 2006) and changes in their spatial distributions may be related to permafrost thaw and belowground carbon losses (Harden et al., 2008; Wilmking et al., 2006). One reason for the relatively low number of observations may be that alpine shrubs are typically less accessible as they often occur at higher elevation and further from roads. However, there can be substantial SOC content in moderately sloped alpine shrub terrain. The northern foothills of the Alaska Range, for example, have a mean 1-m SOC content of 493 Mg ha^{-1} (Schuur et al., 2009). New SOC observations from alpine shrub and tundra landscapes, including thinner soils as endpoints, would improve our understanding of pedogenesis, shrub encroachment, and afforestation processes across climate gradients.

4.2. Soil forming factor controls on SOC accumulations

Our results confirm that air temperature is the dominant control on SOC distribution across Alaska (Ping et al., 1997, 2008b). Previous global and continental scale studies also support that temperature has a negative or non-linear relation to SOC (Amundson, 2001; Guo et al., 2006; Post et al., 1982; Wynn et al., 2006). Temperature-related permafrost and cryoturbation processes enhanced the 1-m SOC content in Arctic Tundra soils so that they were more than double the SOC of the other ecoregions. Various physical processes can account for this. Surface SOC can be subducted into the soil matrix during seasonal freezing and thawing until it reaches the top of the permafrost table where it is essentially protected from mineralization, owing to lower

decomposition at freezing temperatures (Ping et al., 2008b). The thawing of underlying ice-rich permafrost can also cause displacement of soil layers with differing water contents and densities (Swanson, 1996).

Precipitation also plays an important role in SOC accumulation. While SOC increases with increasing temperature and precipitation at lower latitudes in Alaska (cf., Callesen et al., 2003), SOC decreases with increasing temperature at higher latitudes, especially in mineral soils (Fig. 5). In warmer and wetter environments such as the Coastal Rainforest, higher productivity leads to higher organic carbon inputs into the soil matrix. The soils at these locations are also more weathered (as evidenced by their higher clay contents and illuvial horizons; data not shown) which allows for greater stabilization of SOC in the mineral soils.

Considerable variability of SOC within ecoregions can be attributed to the effects of changing topography and soil drainage (Callesen et al., 2003). Previous studies have noted differences in SOC distributions for various landforms, vegetation types, and aspects in Alaska (Michaelson et al., 1996; Ping et al., 2005, 2008b; Troth et al., 1976; Van Cleve et al., 1983, 1993, 1996). The results of this study confirm that improved drainage enhances air temperature effects on soil decomposition and SOC accumulation while impeded drainage diminishes temperature effects. For example, the difference in SOC between the Arctic Tundra and Intermontane Boreal regions for the Uplands was more than twice the difference observed for Lowlands (Table 1; Fig. 5). The impeded drainage at Lowland sites in both ecoregions is partially caused by the presence of permafrost. Soil moisture dampens the seasonal and diurnal amplitude of air temperatures, and plant production and decomposition are highly sensitive to such topographic attributes (e.g. Davidson et al., 1998). Similarly, it appears that impeded drainage was the reason that the Lowlands of the Intermontane Boreal were not very different from the Lowlands of the Coastal Rainforest, whereas for the Uplands the difference was almost three-fold (Table 1; Fig. 5).

Additional controls on SOC accumulation in Alaska, both directly and indirectly related to climate, include interactions of physical > and biotic processes. For example, the 50 cm mineral SOC pool in the Intermontane Boreal region was substantially lower than in other ecoregions, even when our comparisons control for the effects of topography and soil drainage. One explanation for this is that black spruce at poorly-drained sites, in addition to having low productivity, also have roots that are largely constrained to the organic layer, limiting root inputs into the mineral soil (Bonan and Shugart, 1989; Viereck et al., 1983). Further, Lowland black spruce forests typically lack cryoturbation, and therefore exhibit lower mineral SOC content, whereas this process is known to occur on north-facing upland and toeslope soils (Ping et al., 2005). Our dataset has relatively few north-facing profiles under black spruce ($n=6$) which, if accounted for, may increase our estimate of mineral SOC at Upland and Lowland locations. Additionally, within the Intermontane Boreal SOC was higher in locations with permafrost than in locations without in black spruce forests. This confirms similar findings in Alaska by Harden et al. (2006) and Ping et al. (2010) which showed that black spruce forest stands with permafrost were 1.6 times higher in SOC than non-permafrost stands.

Seasonal climatic and biotic interactions may also lower Upland SOC pools of the Intermontane Boreal in several ways. The Intermontane Boreal is a composite of two neighboring yet contrasting soil environments: decomposition-controlled frozen soils to the north (Arctic Tundra) and soils influenced more by plant inputs to the south (Alaska Range Transition). Cumulative fire effects or drought stress (Barber et al., 2000) may be associated with higher MST (Fig. 5) and limit plant growth and organic inputs to soils. Alternatively, both net primary production and decomposition can increase with higher MST because boreal forest productivity is often limited by nutrient release from organic matter mineralization, which increases with soil temperature when water is not limiting. This may be especially true in moderately well-drained soils where soil moisture is optimal for microbial decomposition and plant growth. Indeed, regression models of the Upland forest showed a decrease in mineral SOC with higher MST (Table 3), which may suggest that decomposition outstrips production at more mesic sites. Additionally, Kane and Vogel (2009) found that mineral SOC decreased as soil growing degree days (and productivity) increased in black spruce forests of Interior Alaska.

Importantly, a literal interpretation of the models in Table 3 suggests that if GSL increases substantially (> 20 days) SOC in mineral soils will increase. Climate regimes of higher GSL and MAP may allow for higher productivity, higher organic inputs and, therefore, higher SOC. A situation of increasing SOC may also occur with higher MST and GSL if soil temperatures stabilize due to the insulation of thicker organic layers, but productivity still increases (Table 3). However, increases in net primary production and litter layer inputs from increasing GSL and MAP are also likely to increase nutrient mineralization rates in the surface organic soil layers, affecting bryophyte proliferation and reducing organic layer depths (cf., Mack et al., 2004; Oechel and Van Cleve, 1986). A reduction in organic layer depths (e.g. the InThick model; Table 3) may lead to greater thermal conductance to deeper mineral soil layers and enhanced soil C mineralization. Therefore, without considering the effects of fire, it is possible that Boreal forest mineral SOC could respond both positively and negatively to warmer temperatures where sometimes productivity and sometimes decomposition acts as the dominating control. The response will largely depend on concurrent alterations of soil drainage and the net influence on soil moisture status, plant growth, and soil microbial activity.

Fire is a major disturbance of soil properties and vegetation distributions in the Intermontane Boreal (Kasichke et al., 2002; Yarie, 1981). Fires affect mineral SOC pools by reducing organic layer depth and degrading permafrost, thereby increasing soil temperature, decreasing soil moisture, and increasing CO_2 flux (O'Donnell et al., 2009; O'Neill et al., 2002; Viereck et al., 1983). Combustion represents a significant loss vector for C in Intermontane Boreal systems, on the order of 30 to

60% of NPP over millennial timescales (Harden et al., 2000) and there may be a cumulative long-term effect on SOC which results from frequent burning of material that would otherwise be stabilized in the soil matrix. For example, Fan et al. (2008) simulated decreases of 8 to 78% in SOC over hundreds of years of repeated fires in Alaskan black spruce stands. These scenarios are complicated, however, by existing variable drainage patterns where wetter lowlands soils can reduce the impact of fire (cf., Harden et al., 2001). Our analysis of Sandy Lowland soils (i.e., floodplains) indicated that these predominantly well drained locations are the most affected by fire, apparently causing a 2.7 fold decrease in 1-m SOC. Upland SOC pools are also affected, but apparently more so in the organic layer than in the mineral.

It is difficult to separate fire frequency and seasonal temperature effects on SOC pools of the Intermontane Boreal because they co-vary. Perhaps a useful indicator of these interactions is the MST–MWT variable, where large values indicate higher continentality. Continentality has been associated with fire return interval in Eurasian boreal forests (Sannikov and Goldammer, 1996) and is negatively correlated with MAP in our data set. The interactions of climatic, biotic, and disturbance effects within the Intermontane Boreal may explain why SOC was lower here compared to other ecoregions.

A conceptual equilibrium model of SOC content with Inputs (I) and Decomposition (k) across ecoregions helps to summarize the temperature effects on SOC distribution for Uplands (Table 1; Fig. 6). For SOC in seasonally unfrozen and non-cryoturbated soils, k increases and draws down the SOC pool with increasing MAT. Meanwhile, I also increases with MAT, but not enough to balance SOC losses from the temperature effect on k . Similarly, in addition to the physical mixing of organic rich soils to the deeper profile, the k term dominates the I term in Polar regions. Although a little more than half of the total SOC pool is contained in cryoturbated and permafrost horizons in the Arctic Tundra, the role of cryoturbation over this gradient remains unclear (Bockheim, 2007; Michaelson et al., 1996).

As MAT further increases along the latitudinal gradient the importance of both the I and k terms converge in the Intermontane Boreal (Fig. 6). Permafrost distribution becomes spatially uneven and occurs deeper so that less SOC is permanently frozen. In some cases k is the dominant control and further draws down the pool in response to

Fig. 6. Conceptual equilibrium model of the relative controls on soil carbon content based on Upland data from Table 1. The darkened area represents the total soil carbon content to a 1-m depth and gets darker as soils become warmer and thaw. The dotted lines correspond to the value of the decomposition factor, k , on the left axis (reversed). The solid lines correspond to the value of the organic inputs factor, I , on the right axis. The question marks indicate the poor comparability of Polar cryoturbated pools to other ecoregion soil carbon pools and its uncertainty in response to temperature change. Relative changes in SOC content (Mg ha^{-1}) represented by the darkened areas over the latitude gradient are roughly to scale.

higher decomposition (high MST) in moderately well-drained areas where productivity is low (low GSL) and/or fires are common. In other areas the relative influence of l and k roughly cancel each other out. Still other locations have more favorable GSL, less extreme MST, and perhaps fewer fires, allowing an increase in the SOC pool due to higher productivity relative to k . In the Boreal and Maritime regions where $\text{MAT} > 0$ (and GSL is higher) SOC pools benefit from high productivity and low fire occurrence. Although k increases, l also increases until the equilibrium is reached for these climate conditions (about 230 Mg ha^{-1}). Additionally, organic carbon is more likely to be stabilized in the mineral soils of the Maritime region and biotic and climatic influences result in greater development of parent material. Where drainage is limited, i.e. the Lowlands, these climate-related interactions are somewhat muted or absent. Similarly, local-scale drainage that is influenced by the presence of permafrost and cryoturbation, i.e. north-facing slopes, will be wetter and therefore affected less by these climate–fire interactions in the Boreal.

4.3. Implications of future climate change effects on soil carbon pools

Downscaled future climate projections for Alaska (5 model composite; Scenarios Network for Alaska Planning, <http://www.snap.uaf.edu/>) suggest that MAT may increase by 3.5, 3.2, and 2.4°C from 2009 to 2069 for the Polar, Boreal, and Maritime regions, respectively. Over the same interval, MAP is projected to increase by 70, 40, and 170 mm for the Polar, Boreal, and Maritime, respectively. Historic data from Fairbanks, AK also show that MAT has increased by 1.4°C over 100 years, but without any significant changes in MAP (Wendler and Shulski, 2009). Should Polar landscapes become more Boreal-like, experiencing higher MSTs and fire frequencies, then drainage patterns will adjust accordingly with the result of potentially lowering SOC. Further, lower SOC could result if MAP does not increase in tandem with MAT, leading to higher evapotranspiration and drier soils. Conversely, should some Boreal soils for some reason experience longer growing seasons and either higher precipitation or altered drainage that favors wetter soils, then some soils would potentially increase in SOC if soil temperature remained unchanged. Perhaps most important, therefore, is how future climate change may alter soil moisture patterns, as topographic and parent material effects were demonstrated to ameliorate or exacerbate the effects of temperature on SOC storage (Fig. 5; see also Davidson and Janssens, 2006). Although this study did not focus on the future timing and magnitude of SOC changes in Alaska, a sense of the spatial extent and importance of soil drainage can be inferred. We note that the ecoregions represented in this study account for almost three quarters of Alaska (Fig. 2). More detailed quantification of the overall changes is best left to spatially explicit process-based ecosystem models. Modeling efforts may benefit from considering the variations in SOC for different landforms and vegetation types presented in this study.

The results of this study confirm that Alaska's SOC pool is very large and has important implications for C accounting within the United States and North America, if not globally. For example, when we estimated mean 1-m SOC content in the Arctic Tundra (372 Mg ha^{-1} ; weighted by landform area) it was similar to one study's "North American Arctic" estimate (348 Mg ha^{-1} ; Ping et al., 2008a,b), but higher than another study's global "Tundra" estimate (218 Mg ha^{-1} ; Post et al., 1982). Additionally, Arctic Tundra SOC was 27 and 7 times higher than estimates for "Warm desert" (14 Mg ha^{-1}) and "Tropical woodland and savanna" (54 Mg ha^{-1}), respectively (Post et al., 1982). It should be noted that such large scale comparisons can only be done imperfectly and with very high uncertainty because of different approaches to calculating both point and regional scale estimates of SOC. In general, there is a great need for reports of SOC to use enhanced data sets that not only capture site variability but that also consistently derive values in ways that minimize uncertainties from measurements and extrapolations to larger scales.

5. Conclusions

The soil carbon database used in this study was created as a resource for investigations into the importance of Alaskan soils in global climate change. From the database we have identified data gaps that limit our ability to scale up observational data and compare them to ecosystem model outputs. Other landforms and vegetation types that contain lower SOC, such as Upland shrubby landscapes, should not be ignored if their areal coverage may result in the accumulation of significant SOC stocks. Samples that fill in the longitudinal change in SOC from the Bering Taiga region to the Intermontane Boreal will also help to assess whether SOC changes over climatic gradients follow expected patterns, or if they deviate, and why. Finally, as the database grows to include more data from SOC in wetlands and permafrost for a variety of ecosystems, our understanding of SOC response to climate change will continue to improve.

Despite data gaps, it is clear that because most of Alaska's soils occur over a wide range of MAT under 0°C , that MAT exerts the first order effect on SOC spatial distribution across the state. Additionally, it is clear that the degree of climatic influence on SOC pools is variable among landforms of different relief and texture related to parent material. Adding to this complexity are additional controls of aspect, permafrost presence, and stand age that interact in non-linear patterns. Some basic inferences about how seasonal climate and disturbance affects SOC pools can be drawn by comparing ecoregions. Intermontane Boreal SOC content is lower than the other regions probably because of its continental climate that results in harsh winters, short growing seasons, low MAP, high MST, and high fire frequencies. As a conceptual model, the Intermontane Boreal is the transition between SOC pools which are dominated by physical and abiotic processes (i.e., cryoturbation and permafrost) and SOC pools that increase due to biotic factors related to higher organic inputs (i.e., productivity).

Determining the balance of carbon losses and gains from soils at high-latitudes, and their potential climatic feedbacks, depends to a large degree on how accurately the spatial heterogeneity of SOC pools can be scaled up and applied in global climate models. In this first order assessment of spatial heterogeneity in SOC pools across three very different high-latitude climatic regimes, we have aimed to discretely quantify SOC pools according to different ecoregion, landform, and ecosystem types. Our results suggest that the response of SOC pools to climate changes will not be of the same magnitude, and perhaps not even the same direction, for all high-latitude soils. Patterns of SOC accumulation in relation to upland and lowland ecosystems should be carefully considered in the modeling of terrestrial carbon cycling and the prediction of the future balance of carbon in Alaska and abroad. These issues deserve special attention given the enormous amount of carbon contained in high-latitude soils and their role in the global carbon cycle.

Acknowledgements

This assessment, and the workshop which led to the creation of the soil carbon database used in the assessment, was sponsored by the U.S. Geological Survey funded research on "Assessing the Role of Deep Soil Organic Carbon in Interior Alaska: Data, Models, and Spatial/Temporal Dynamics". The help of Deb Agarwal and Catharine Van Ingen from Lawrence Berkeley National Labs and Microsoft Research were essential for the creation and logistical support of the soil carbon database. We also acknowledge the very helpful reviews given by Bronwen Wang, Shuguang Liu, Ingeborg Callesen and one anonymous reviewer.

Appendix 1. Gap-filling procedure

Negative exponential models that predict bulk density from %C were applied for missing data in all mineral soil horizons except arctic soils (Appendix Table 1). There were some rare cases when samples had

bulk density data available but not %C and were gap-filled using a modified equation (Eq. 3b). Models of SOC or bulk density were better fit when the horizon designation was known (Eqs. 4–6). When there was no horizon designation, and the horizon was only known to be organic (SOC_o) or mineral (BD_{min}), then general models were applied (Eqs. 3a, 9). Frozen mineral soil bulk density of mainly Boreal profiles was predicted separately and was not distinguished by horizon designation (Eq. 7). In contrast to bulk density measurements of mineral soils, bulk density in organic soils was not well-predicted by non-linear models of %C. The best approach in this case proved to be the direct prediction of SOC content from horizon thickness, *Th*, using a weighted least squares regression and by horizon designation (Eqs. 10–12).

Adjustment equations were applied to bulk density and organic carbon concentration measurements from the National Cooperative Soil Survey (NCSS) in order to make them comparable to other datasets. Bulk density measurements by the NCSS were done by the clod method, *BD_{clod}* (Soil Survey, 1996) whereas all the other bulk densities of this study were measured by the cylinder method, *BD_{core}*. The clod method yields consistently higher values than the cylinder method (Calhoun et al., 2001; VanRemortel and Shields, 1993). To correct for this difference in mineral soils, the same equation used in VanRemortel and Shields (1993) was applied (Eq. 1). A similar correction equation has not been published for organic soils to our knowledge. Yet, organic layer bulk densities measured by the clod method were between 1.4 and 5 times greater than by the core method (using a subset of data including black spruce stands only). Therefore, organic horizon bulk density measurements by the clod method were excluded and treated as if they were missing data. For organic carbon concentration, some NCSS data (26% of the total dataset) was measured only by the Walkley–Black method, %C_{org} (e.g. method 6A1c; Burt, 2004). The rest of the dataset was measured by dry combustion, %C_{tot} (methods 4H2a or 6A2d; Burt, 2004). Therefore, a relation was found so that in cases where only %C_{org} data was available, it was adjusted to more closely match %C_{tot} (Eq. 2).

In the Arctic Tundra many profiles were highly cryoturbated which requires specialized methods of calculating SOC content (e.g. Michaelson et al., 1996). The 1-m SOC estimates for highly cryoturbated profiles in this study included only those with published values (Bockheim, 2007; Bockheim and Hinkel, 2007; Bockheim et al., 1999; Michaelson et al., 1996; Ping et al., 1997) and therefore no bulk density predictions were necessary. Non-cryoturbated soils whether organic or mineral, or frozen or unfrozen, were predicted by a separate relation specific to arctic soils (Eq. 13; see also Bockheim et al., 2003 for a similar equation).

Appendix Table 1
Gap-filling equations.

Equations	adj. R ²
Adjustment equations	
1. $BD_{adj} = BD_{core} = \frac{BD_{clod} - 0.068}{1.011}$	0.98
2. $\%C_{adj} = \%C_{tot} = 0.2107 + 0.8830 * \%C_{org}$	0.98
Prediction equations for mineral soils	
3a. $BD_{min} = 0.4189 + e^{-0.1868 * \%C_{tot}}$	0.64
3b. $\%C_{pred} = \frac{\log(BD_{core} - 0.4223)}{0.1890}$	0.54
4. $BD_A = 0.3417 + e^{-0.1712 * \%C_{tot}}$	0.59
5. $BD_B = 0.4671 + e^{-0.1915 * \%C_{tot}}$	0.52
6. $BD_C = 0.6560 + e^{-0.2466 * \%C_{tot}}$	0.49
7. $BD_{fzn} = 0.3105 + e^{-0.1400 * \%C_{tot}}$	0.48
Prediction equations for organic soils	
9. $SOC_o = 0.0085 + 0.0334 * Th$	0.47
10. $SOC_{oi} = 0.0109 + 0.0183 * Th$	0.38
11. $SOC_{oe} = 0.0269 + 0.0411 * Th$	0.59
12. $SOC_{oi} = 0.0743 + 0.0354 * Th$	0.63
Prediction equation for all arctic soils—frozen or unfrozen, mineral or organic	
13. $BD = 0.0577 + e^{-0.0694 * \%C_{tot}}$	0.60
